# **Part III Spectrum Estimation** 3.2 Parametric Methods for Spectral Estimation

Electrical & Computer Engineering North Carolina State University

Acknowledgment: ECE792-41 slides were adapted from ENEE630 slides developed by Profs. K.J. Ray Liu and Min Wu at the University of Maryland, College Park. Contact: chauwai.wong@ncsu.edu.

## Summary of Related Readings on Part-III

- Overview Haykins 1.16, 1.10
- 3.1 Non-parametric method

Hayes 8.1; 8.2 (8.2.3, 8.2.5); 8.3

3.2 Parametric method

Hayes 8.5, 4.7; 8.4

**3.3 Frequency estimation** Hayes 8.6

#### Review

- On DSP and Linear algebra: Hayes 2.2, 2.3
- On probability and parameter estimation: Hayes 3.1 3.2

# <u>Motivation</u>

- Implicit assumption by classical methods
  - Classical methods use Fourier transform on either windowed data or windowed autocorrelation function (ACF)
  - Implicitly assume the unobserved data or ACF outside the window are zero => not true in reality
  - Consequence of windowing: smeared spectral estimate (leading to low resolution)
- If prior knowledge about the process is available
  - We can use prior knowledge and select a good model to approximate the process
  - Usually need to estimate fewer model parameters (than nonparametric approaches) using the limited data points we have
  - The model may allow us to better describe the process outside the window (instead of assuming zeros)

## **General Procedure of Parametric Methods**

- Select a model (based on prior knowledge)
- Estimate the parameters of the assumed model
- Obtain the spectral estimate implied by the model (with the estimated parameters)

#### Spectral Estimation using AR, MA, ARMA Models

- Physical insight: the process is generated/approximated by filtering white noise with an LTI filter of rational transfer func *H*(*z*)
- Use observed data to obtain estimates  $\hat{r}(k)$  for small k's
  - $\hat{r}(k)$  of larger lags are implicitly extrapolated by the estimated model
- Relation between r(k) and filter parameters  $\{a_k\}$  and  $\{b_k\}$ 
  - PARAMETER EQUATIONS from Section 2.1.2(6)
  - Solve the equations using  $\hat{r}(k)$  to obtain estimated filter parameters
  - Use the p.s.d. implied by the estimated model as spectral estimate
- Deal with nonlinear parameter equations
  - Try to convert/relate them to the AR models that have linear equations

#### **Review: Parameter Equations**

<u>Yule-Walker equations</u> (for AR process)

$$\begin{cases} -\sum_{k=1}^{P} a(k) T_{x}[-k] + \sigma^{2} \\ -\sum_{k=1}^{P} a(k) T_{x}[-k] + \sigma^{2} \\ for k=0 \\ -\sum_{k=1}^{P} a(k) T_{x}[k-k] \\ for k \ge 1 \\ \end{cases} \begin{bmatrix} T_{x}(0) T_{x}(1) - - T_{x}(-P+1) \\ T_{x}(0) - - T_{x}(-P+1) \\ T_{x}(0) - - T_{x}(-P+1) \\ T_{x}(-P+1) - - T_{x}(-P+1) \\ T_{x}(-P) \\ T_{x}(-P) \\ \end{bmatrix} \begin{bmatrix} a(1) T_{x}(1) \\ a(2) \\ T_{x}(2) \\ T_{x}(2) \\ T_{x}(2) \\ T_{x}(-P) \\ T_{x}(-P) \\ T_{x}(-P) \end{bmatrix} = - \begin{bmatrix} T_{x}(1) \\ T_{x}(2) \\ T_{x}(2) \\ T_{x}(2) \\ T_{x}(2) \\ T_{x}(2) \\ T_{x}(-P) \\ T_{x}(-P) \\ T_{x}(-P) \end{bmatrix} = - \begin{bmatrix} T_{x}(1) \\ T_{x}(2) \\ T_{x}(2) \\ T_{x}(2) \\ T_{x}(P) \\ T_{x}(P) \end{bmatrix}$$

MA model

$$\begin{split} & \sum_{k=0}^{k} \sum_{k=1}^{k} \sum_{k=0}^{k} \sum_{k=0}^{k}$$

## 3.2.1 AR Spectral Estimation

#### (1) Review of AR process

- The time series  $\{x[n], x[n-1], ..., x[n-m]\}$  is a realization of an AR process of order *M* if it satisfies difference equation  $x[n] + a_1 x[n-1] + ... + a_M x[n-M] = v[n]$ where  $\{v[n]\}$  is a white noise process with variance  $\sigma^2$ .
- Generating an AR process with parameters  $\{\hat{a}_i\}$ :

Recall: the p.s.d. of an AR process {*x*[*n*]} is given by

## **Procedure of AR Spectral Estimation**

- Observe the available data points x[0], ..., x[N-1], and Determine the AR process order p
- Estimate the autocorrelation functions (ACF) k=0, ..., p

Biased (low variance)  

$$\hat{r}(k) = \frac{1}{N} \sum_{n=0}^{N-1-k} x[n+k] x^*[n]$$
Unbiased (may not non-neg. definite)  

$$\hat{r}(k) = \frac{1}{N-k} \sum_{n=0}^{N-1-k} x[n+k] x^*[n]$$

- Solve {â<sub>i</sub>} from the Yule-Walker equations (or the normal equations of forward linear prediction)
  - Recall for an AR process, the normal equation of FLP is equivalent to the Yule-Walker equation
- Obtain estimated power spectrum:

## 3.2.2 Maximum Entropy Spectral Estimation (MESE)

- Viewpoint: Extrapolations of ACF
  - $\{\hat{r}[0], ..., \hat{r}[p]\}\$  is known; there are generally an infinite number of possible extrapolations for r(k) at larger lags
  - As long as  $\{r[p+1], r[p+2], ...\}$  guarantee that the correlation matrix is non-negative definite, they all form valid ACFs for w.s.s.
- Maximum entropy principle
  - Perform extrapolation s.t. the time series characterized by the extrapolated ACF has maximum entropy
  - i.e., the time series will be the least constrained thus most random one among all series having the same first (p+1) ACF values

# => Maximizing entropy leads to estimated p.s.d. be the smoothest one

- Recall white noise process has flat p.s.d.

## **MESE for Gaussian Process: Formulation**

For a Gaussian random process, the entropy per sample is proportional to

$$\int_{-\frac{1}{2}}^{\frac{1}{2}}\ln P(f)df$$

Thus the max entropy spectral estimation is  

$$\max \int_{-\frac{1}{2}}^{\frac{1}{2}} \ln P(f) df$$
subject to  

$$\int_{-\frac{1}{2}}^{\frac{1}{2}} P(f) e^{j2\pi f k} df = \hat{r}(k), \quad \text{for } k = 0, 1, ..., p$$

## **MESE for Gaussian Process: Solution**

Using the Lagrangian multiplier technique, the solution can be found as

$$\hat{P}_{\rm ME}(f) = \frac{\sigma^2}{\left|1 + \sum_{k=1}^p \hat{a}_k e^{-j2\pi f k}\right|^2}$$

where  $\{\hat{a}_k\}$  are found by solving the Yule-Walker equations given the estimated ACF values  $\hat{r}[0], ..., \hat{r}[p]$ .

- For Gaussian processes, the MESE is equivalent to AR spectral estimator and the  $\hat{P}_{ME}(f)$  is an all-pole spectrum
  - Different assumptions on the process: Gaussian vs. AR processes

#### 3.2.3 MA Spectral Estimation

An MA(q) model

$$x[n] = \sum_{k=0}^{q} b_k v[n-k] \quad \Rightarrow \quad B(z) = \sum_{k=0}^{q} b_k z^{-k}$$

can be used to define an MA spectral estimator

$$\hat{P}_{\rm MA}(f) = \sigma^2 \left| 1 + \sum_{k=1}^{q} \hat{b}_k e^{-j2\pi f k} \right|^2$$

Recall important results on MA process:

- (1) The problem of solving for  $b_k$  given  $\{r(k)\}$  is to solve a set of nonlinear equations;
- (2) An MA process can be approximated by an AR process of sufficiently high order.

#### **Basic Idea to Avoid Solving Nonlinear Equations**

Consider two processes:

- Process #1: an approximated high-order AR process in the observed data x[n]
  - We model x[n] as a high-order AR process generated by  $1/\hat{A}(z)$  filter

• Process #2: an MA process y[n] generated by  $\hat{A}(z)$  filter

- Since we know  $\hat{A}(z)$ , we can obtain y[n]'s autocorrelation values  $r_y(k)$
- We model process #2 as an AR(q) process => the filter would be  $1/\hat{B}(z)$

# **Use AR Model to Help Finding MA Parameters**

- For simplicity, we consider the real coefficients for the MA model.

Note 
$$P_{MA}(z) = \sigma^2 B(z) B(z^{-1})$$

To approximate it with an AR(L) model, i.e.,

- The RHS represents power spectrum of an AR(q) process
- The inverse ZT of LHS is the ACF of the AR(q) process

#### **Recall: ACF of Output Process After LTI Filtering**

#### **Use AR to Help Finding MA Parameters (cont'd)**

Let  $x[n] = w[n] \sim N(0, \sigma_w^2)$  i.i.d., and  $h[n] = \hat{a}_n$ , we have

$$r_y(k) = \sigma_w^2 \sum_{n=0}^{L-k} \hat{a}_n \hat{a}_{n+k} \qquad \text{for lag } k$$

- → Knowing autocorrelation sequence  $r_y(k)$ , the best AR coefficients  $\{\hat{b}_k\}$  for process #2 can be obtained by direct matrix inverse or Levinson-Durbin recursion.
- Note that the best AR coefficients for process #2 are actually the best MA coefficients for process #1.

## **Durbin's Method**

1. Use Levinson-Durbin recursion and solve for

- We first approximate the observed data sequence  $\{x[0], ..., x[N]\}$ with an AR model of high order (often pick L > 4q)
- We use biased ACF estimator (1/N) to ensure nonnegative definiteness and smaller variance than unbiased estimator [1/(N-k)]

2. Fit an AR(q) model to the data sequence  $\{1, \hat{a}_1, \hat{a}_2, ..., \hat{a}_L^{\dagger}\}$ 

$$\begin{bmatrix} \widehat{\Gamma}_{a}(0) & \widehat{\Gamma}_{a}(1) & --- & \widehat{\Gamma}_{a}(g-1) \\ \widehat{\Gamma}_{a}(1) & \widehat{\Gamma}_{a}(0) & \widehat{\Gamma}_{a}(g-2) \\ \vdots & \vdots \\ \widehat{\Gamma}_{a}(g-1) & -- & -- & \widehat{\Gamma}_{a}(0) \end{bmatrix} \begin{bmatrix} \widehat{b}_{1} \\ \vdots \\ \widehat{b}_{g} \end{bmatrix} = - \begin{bmatrix} \widehat{\Gamma}_{a}(1) \\ \vdots \\ \widehat{b}_{g} \end{bmatrix}$$
where  $\widehat{\Gamma}_{a}(K) = \frac{1}{L+1} = \sum_{n=0}^{L-K} \widehat{A}_{n} \widehat{A}_{n+K}$ 

- The result  $\{b_i\}$  is the estimated MA parameters for original  $\{x[n]\}$ 

- Note we add 1/(L+1) factor to allow the interpretation of  $r_a(k)$  as an autocorrelation function estimator

#### 3.2.4 ARMA Spectral Estimation

Recall the ARMA(p, q) model

$$x[n] = -\sum_{k=1}^{p} a_k x[n-k] + \sum_{k=0}^{q} b_k v[n-k]$$

We define an ARMA(p, q) spectral estimator

$$\hat{P}_{\text{ARMA}}(f) = \hat{\sigma}^2 \frac{\left|1 + \sum_{k=1}^{q} \hat{b}_k e^{-j2\pi f k}\right|^2}{\left|1 + \sum_{k=1}^{p} \hat{a}_k e^{-j2\pi f k}\right|^2}$$

## **Modified Yule-Walker Equations**

Recall the Yule-Walker Eqs. for ARMA(p, q) process

$$\begin{cases} \Gamma_{x}[k] = - \oint_{l=1}^{P} a[l] \Gamma_{x}[k-l] + \int_{l=0}^{1} \int_{k=0}^{2\pi} h^{*}[l] b[l+k] \\ k=0,1,\dots,p \end{cases}$$

$$\Gamma_{x}[k] = - \int_{k=1}^{P} a[l] \Gamma_{x}[k-l] , \quad k \ge q+1.$$

We may use equations for  $k \ge q+1$  to solve for  $\{a_i\}$ 

$$\begin{bmatrix} \Gamma(\mathcal{X}) & \Gamma(\mathcal{X}^{-1}) & - & - & \Gamma(\mathcal{X}^{-1} + 1) \\ \Gamma(\mathcal{X}^{+1}) & \Gamma(\mathcal{X}^{-1}) & \vdots \\ \vdots & \vdots & \vdots \\ \Gamma(\mathcal{X}^{+1} + 1) & - & - & - & \Gamma(\mathcal{X}^{-1} + 1) \\ \Gamma(\mathcal{X}^{+1} + 1) & - & - & - & \Gamma(\mathcal{X}^{-1} + 1) \\ \hline = & - & \left[ \begin{array}{c} \Gamma(\mathcal{X}^{+1} + 1) \\ \Omega_{\mathcal{X}} \\ \Omega_{\mathcal{X}} \end{array} \right] = - \begin{bmatrix} \Gamma(\mathcal{X}^{+1} + 1) \\ \vdots \\ \Gamma(\mathcal{X}^{+1} + 1) \\ \Omega_{\mathcal{X}} \end{array} \right] = - \begin{bmatrix} \Gamma(\mathcal{X}^{+1} + 1) \\ \vdots \\ \Gamma(\mathcal{X}^{+1} + 1) \\ \Omega_{\mathcal{X}} \end{bmatrix} = - \begin{bmatrix} \Gamma(\mathcal{X}^{+1} + 1) \\ \vdots \\ \Gamma(\mathcal{X}^{+1} + 1) \\ \Omega_{\mathcal{X}} \end{bmatrix} = - \begin{bmatrix} \Gamma(\mathcal{X}^{+1} + 1) \\ \vdots \\ \Gamma(\mathcal{X}^{+1} + 1) \\ \Omega_{\mathcal{X}} \end{bmatrix} = - \begin{bmatrix} \Gamma(\mathcal{X}^{+1} + 1) \\ \vdots \\ \Gamma(\mathcal{X}^{+1} + 1) \\ \Gamma(\mathcal{X}^{+1} + 1) \end{bmatrix} = - \begin{bmatrix} \Gamma(\mathcal{X}^{+1} + 1) \\ \vdots \\ \Gamma(\mathcal{X}^{+1} + 1) \\ \Gamma(\mathcal$$

#### Estimating ARMA Parameters

1. By solving the modified Yule-Walker eqs., we obtain

$$\hat{A}(z) = 1 + \sum_{k=1}^{p} \hat{a}_{k} z^{-k}$$

2. We eliminate the AR component by filtering x[n] with FIR filter  $\hat{A}(z)$  to obtain an approximate MA(q) process:

$$\hat{A}(z)X(z) = \hat{A}(z)\frac{B(z)}{A(z)}W(z) \approx B(z)W(z)$$

3. Coefficients  $\{b_k\}$  can be estimated by Durbin's method.

## Extension: LSMYWE Estimator

- Performance by solving *p* modified Yule-Walker equations followed by Durbin's method
  - May yield highly noisy spectral estimates (esp. when the matrix involving ACF is nearly singular due to poor ACF estimates)
- Improvement: use more than p equations to solve  $\{\hat{a}_1, \dots, \hat{a}_p\}$  in a least squared sense
  - Use Yule-Walker equations for k = (q+1), ..., M:  $\min ||\mathbf{t} \mathbf{Sa}||^2$
  - Least-squares solution:  $\hat{\mathbf{a}} = (\mathbf{S}^H \mathbf{S})^{-1} \mathbf{S}^H \mathbf{t}$
  - Then obtain  $\{b_k\}$  by Durbin's method

#### → "Least-Squares Modified Yule-Walker Equations" (LSMYWE)

Ref: review in Hayes' book Sec.2.3.6 on least square solution

## **Comparison of Different Methods: Revisit**

 Test case: a process consists of narrowband components (sinusoids) and a broadband component (AR)

$$- x[n] = 2\cos(\omega_1 n) + 2\cos(\omega_2 n) + 2\cos(\omega_3 n) + z[n],$$
  
where  $z[n] = -a_1 z[n-1] + v[n], a_1 = -0.85, \sigma_v^2 = 0.1,$   
 $\omega_1/2\pi = 0.05, \omega_2/2\pi = 0.40, \omega_3/2\pi = 0.42.$ 

- N=32 data points are available → periodogram resolution f = 1/32
- Examine typical characteristics of various non-parametric and parametric spectral estimators

(Fig.2.17 from Lim/Oppenheim book)

NCSU ECE792-41 Statistical Methods for Signal Analytics

Parametric spectral estimation [25]

## 3.2.5 Model Order Selection

- The best way to determine the model order is to base it on the physics of the data generation process
- Example: speech processing
  - Studies show the vocal tract can be modeled as an all-pole filter having 4 resonances in a 4kHz band, thus at least 4 pairs of complex conjugate poles are necessary
    - → Typically 10–12 poles are used in an AR modeling for speech
- When no such knowledge is available, we can use some statistical test to estimate the order
- Ref. for in-depth exploration: "Model-order selection," by P. Stoica and Y. Selen, IEEE Signal Processing Magazine, July 2004.

## **Considerations for Order Selection**

#### Modeling error

- Modeling error measures the (statistical) difference between the true data value and the approximation by the model
  - e.g., estimating linear prediction MSE in AR modeling
- Usually for a given type of model (e.g., AR, ARMA), the modeling error decreases as we increase the model order
- Balance between the modeling error and the amount of model parameters to be estimated
  - The number of parameters that need to be estimated and represented increases as we use higher model order → Cost of overmodeling
  - Can balance modeling error and the cost of going to higher model by imposing a penalty term that increases with the model order

# **A Few Commonly Used Criteria**

- Akaike Information Criterion (AIC)
  - A general estimate of the Kullback-Leibler divergence between assumed and true p.d.f., with an order penalty term increasing linearly
  - Choose the model order that minimize AIC

$$AIC(i) = N \ln \varepsilon_{p} + 2i$$
  
size of  $\checkmark$  model error model order:  
available data model error  $i = p$  for AR( $p$ )  
 $i = p + q$  for ARMA( $p, q$ )

- Minimum Description Length (MDL) Criterion
  - Impose a bigger penalty term to overcome AIC's overestimation
  - Estimated order converges to the true order as N goes to infinity

 $\mathrm{MDL}(i) = N \ln \varepsilon_p + (\log N)i$
